ABSTRACT

It was found that date seeds are suitable for biochar production due to their low moisture content 8.92%, low ash yield 1.05%, and high organic matter content 78.3%. The biochar was produced by pyrolysis at 350, 450 and 550°C. The effect of pyrolysis temperature on the physicochemical characteristics of biochar was investigated. It was found that the porosity, water holding capacity, ash content, pH, organic matter, fixed carbon, and the elemental content of Na, K, Ca, Mg, Fe, Mn, P, Zn, Ba, Cr, Cu, Ni, Pb, Ti, and V were increased along with pyrolysis temperature. Meanwhile, the biochar yield, bulk density, and the total content of N and S were decreased. The biochar was tested as a sustainable adsorbent to investigate the adsorption of Cd from contaminated water. The adsorption isotherms of Cd on biochar were determined based on Langmuir equation. The maximum adsorption of Cd at 25°C and pH 7 were 667, 714, and 833 mg/kg for the biochars produced at 350, 450, and 550°C, respectively. On the basis of the physicochemical characteristics of the biochar and the findings from Langmuir equation that showed the biochar produced at 550°C has the highest adsorption capacity for Cd, the desorption/adsorption experiment was carried out using the biochar produced at 550°C. The adsorption of Cd by biochar was directly proportional to the Cd concentrations. It was increased from 0.009 mmol/0.5g at 0.01 mmol Cd to 0.12 mmol/0.5g at 0.2 mmol Cd concentration. The desorption of Cd from biochar was increased proportionally to cadmium concentrations from 0.01 to 0.05 mmol and became constant above 0.05 mmol, regardless of the increment of cadmium concentrations. High retention potential for the cadmium that adsorbed within the biochar was proven in this study with desorption/adsorption percentage of 16%. These findings provide a successful example of date seeds converting into the sustainable adsorbent for Cd removal from aquatic environment to achieve the conception of eco-friendly production, which should be studied further.

Keywords: biochar, date seeds, pyrolysis, cadmium, adsorption, isotherm, spectroscopy.

INTRODUCTION

The heavy metals contamination into the environment caused by human activities (industry, agriculture, and mining) is a crucial worry for water, wastewater, and soils around the world (Usman et al., 2016). There are ecological and human health risks associated with toxic metals in water (Laniyan and Adewumi, 2021). There is a significant positive correlation between the toxic metal contents (Cd for example) in the soil and those in the plants (Ugulu et al., 2021). Human activities (industry, transportation, and agriculture) have caused toxic Cd pollution resulting in ecological risk to agricultural soil, the Cd

ratio was exceeding the soil background value with 99.9% (Duan et al., 2021).

Usman et al. (2016) mentioned that Cadmium is very toxic to living organisms even at low concentrations and could be carcinogenic if present in water; thus, its remediation is necessary. Many techniques were used for removing heavy metals (ion-exchange, membrane filtration, adsorption, electrochemical, and chemical precipitation), each method has inherent advantages as well as one or more issues, challenges and limitations in application (Manna and Bhaumik, 2021).

The adsorption method has advantages in treating wastewater from heavy metals

regarding its high efficiency and cheap cost (Cheng et al., 2021; Lucaci et al., 2020). The common adsorbent for heavy metal remediation from water is the activated carbon, which is expensive. Therefore, more attention needs to be devoted by scientists to searching low cost adsorbent with high ability to retain metals, which is one of the current challenges for scientists (Ungureanu et al., 2020).

Date trees are one of the most abundant trees worldwide, which generated beneficial wastes that can be reused in industry (Nasir et al., 2021). Mathijsen (2021) reported that the Middle East and North Africa regions have an estimated 140 million date trees. In consequence, the consumption of dates is common in these countries on a daily basis, in addition to its entry into the food industries. Thus, huge quantities of date seeds are produced and can be used in industries as a raw and ecofriendly material. Therefore, date seeds could be a good resource for biochar production, which can be used as metal absorbent. Biochar showed a high potential in treating wastewater from heavy metals due to its high porosity and the existence of various functional groups (Cheng et al., 2021). Other studies claimed that biochar was effective with high affinity to remove heavy metals from aqueous environment (Li et al., 2017; Trakal et al., 2014). Within context, many adsorbents were produced through pyrolysis and applied as an effective cheap technique for water purification (De Gisi et al., 2016). Singh et al. (2021) reported that the biochars produced from organic waste can be used as good green sorbents for the remediation of heavy metals from aquatic environment. However, the efficiency of biochar for removal of heavy metals from aqueous solutions dependent mainly on its physical and chemical properties that can be controlled by many factors including raw material source and the pyrolysis conditions (Zhao et al., 2021).

In spite of the worldwide use of biochar as a remediation agent for the environment, more studies regarding the raw material suitability for biochar production, optimization of biochar production to achieve the best physicochemical characteristics as adsorbent agent, are needed. Therefore, this study was aimed to produce biochars from date seeds and to evaluate its efficiency on Cd removal of from aqueous solutions.

MATERIAL AND METHODS

Raw materials and sample preparation

Date seeds (DS) were obtained locally after removing the date fruits. The seeds were washed with deionized water and air-dried until reaching constant weight. The seed were then stored in desiccator for biochar production and further analysis.

Date seeds physicochemical characteristics

The seeds were weighted initially to obtain the wet weight, and then dried for 24 h at 105°C in an oven. The dried seed were then turned to ashes by pyrolysis using muffle furnace at 350, 450, and 550°C for 2 h. The physicochemical parameters: moisture content, ash content, and organic matter were calculated using the equations 1, 2, 3, and 4 according to (Babu et al., 2021 and Liu et al., 2019). Fixed carbon content was measured by calculating the remaining residues including the non-volatile and minerals after releasing the volatile matter (Mahdi et al., 2015).

$$\text{Moisture content (\%)} = \left(\frac{\text{Wet}_{wt} - \text{Dry}_{wt}}{\text{Wet}_{wt}} \right) * 100\% \quad (1)$$

$$\text{Ash content (\%)} = \left(\frac{\text{Ash}_{wt}}{\text{Dry}_{wt}} \right) * 100\% \quad (2)$$

$$\text{Organic matter} = \text{Dry}_{wt} - \text{Ash}_{wt} \quad (3)$$

$$\text{Organic matter (\%)} = \left(\frac{\text{Organic matter}}{\text{Dry}_{wt}} \right) * 100\% \quad (4)$$

where: wet_{wt} is the sample weight before drying, Dry_{wt} is the sample weight after drying at 105°C for 24 h, and Ash_{wt} is the ash weight after pyrolysis for 2 h.

Biochar production and analysis

The DS biochar was produced by pyrolysis of dried dates seeds in absence of oxygen using closed porcelain crucible in the muffle furnace at different temperatures 350, 450, and 550°C for 2 h (Jerley et al., 2021). The DS biochar has been crushed and sieved to particle size of 2 mm to be used in the later experiments. The yield of DS biochar was measured using equation 5 (Mohawesh et al., 2018 and Angin, 2013).

$$\text{Biochar yield (\%)} = \left(\frac{\text{Weight of biochar}}{\text{Weight of dry sample}} \right) * 100\% \quad (5)$$

The microstructure and morphology of DS biochar was investigated by scanning electron microscopy (SEM) with energy dispersive X-ray analysis (EDX).

The porosity and water absorption of the DS biochar were measured following the Archimedes method according to the standard method (ASTM C20) as mentioned by (Sutcu et al., 2019) by placing the well-dried DS biochar in boiling water for 2 h then soaked in water for 12 h. Thereafter, equations 6 and 7 were used to determine the above-mentioned parameters:

$$\begin{aligned} \text{Porosity (\%)} &= \left(\frac{\text{Open pore volume}}{\text{Total volume}} \right) * 100\% \\ &= \left(\frac{\text{Sat}_{wt} - \text{Dry}_{wt}}{\text{Sat}_{wt} - \text{Sus}_{wt}} \right) * 100\% \end{aligned} \quad (6)$$

where: Dry_{wt} is the biochar weight after drying at 105°C for 24 h, Sat_{wt} is the biochar saturated weight after boiling in water for 2 h, and Sus_{wt} is the biochar suspended weight while suspending in water for 12 h.

The pH value for the DS biochar was investigated according to Greenberg (2005). Bulk density was determined using an analytical balance and a graduated cylinder. The bulk density was detected by weighing the well-known volume of uncompacted DS biochar particles after taping the cylinder vigorously on a wooden table until reaching a constant volume. It was calculated as mass of the biochar particles per volume of uncompacted biochars (Liao and Thomas, 2019).

For elemental content, the biochar was analyzed by means of (Inductively coupled plasma-mass spectrometry, ICP-MS). For that purpose, each of the biochar samples produced under different temperatures (350 , 450 , and 550°C), were pyrolyzed in the muffle furnace at 550°C for 2 h to produce ash. Thereafter, 1 ml of Bismuth 200 ppm was added to 0.1 g of each ash sample into teflon vials as external standard. The samples were digested by concentrated acid mixture HNO_3 : HCl : HF with ratio of 2:6:2 (v/v), respectively. The digestion was carried out using hotplate at 75°C , 100°C , 120°C , 150°C , and 200°C for 5, 10, 10, 10, and 20 min, respectively. The digested samples were filtered through syringe filters $0.45 \mu\text{m}$ pore size (PTFE, Sartorius, Göttingen/Germany), the filtrate was then diluted to 50 ml by 2% nitric acid and analyzed for elements by means of ICP-MS (ELAN 9000, Perkin-Elmer SCIEX).

Sorption isotherm, adsorption, and desorption for Cd by DS biochar

Cadmium was chosen to be a model to study the heavy metal adsorption by DS biochar for

two reasons. First; it was not detected within the DS biochar, and the second; it is always detected in industrial wastewaters; therefore, it could find its way into the environment, food chain and thus human systems.

The DS biochar produced at 350 , 450 , and 550°C were tested for the sorption isotherm experiment. The adsorption of Cd by DS biochar was investigated for the sorption capacity and equilibrium. For that reason, a stock solution of Cd with concentration of 10 mmol was prepared by dissolving the proper weight of cadmium nitrate (Merck, Darmstadt, Germany) in one liter of deionized water. 0.5 gram of DS biochar was added to 100 ml flasks volume containing 50 ml of different Cd concentrations 0.01, 0.02, 0.05, 0.1 and 0.2 mmol, the pH was adjusted to 7. All flasks were rotated with 50 rpm at 25°C overnight and followed by centrifugation for 10 min at 3500 rpm. The equilibrium solutions (supernatants) were filtered by $0.45 \mu\text{m}$ syringe filters (Palágyi et al., 2005). The filtrate solutions were acidified with 2% HNO_3 (v/v) and analyzed for Cd using Atomic Absorption Spectroscopy (Shimadzu, AA-7000, Japan). After collecting and filtrating the supernatant, all flasks were weighted again with the DS biochar and the remaining cadmium solution. The remaining cadmium solution that will be used later in desorption calculations was calculated by subtracting the weight of dried DS biochar and the weight of empty flasks from the total weight, to be used in the calculations of desorption later.

The experiments of desorption were performed for the DS biochar that was produced at 550°C and used previously in the adsorption experiments due to its physicochemical properties regarding WHC and porosity percentage as well as its higher ability to adsorb more Cd than the biochars produced at 350 and 450°C . For that reason, 5 mL of ammonium nitrate with 1 M concentration (Merck, Darmstadt, Germany) were added to the flasks containing the DS biochar from the adsorption experiment. The mixtures were rotated for 24 h with 50 rpm at 25°C then centrifuged for 10 min at 3500 rpm. The supernatants were filtered by $0.45 \mu\text{m}$ syringe filters (Rao et al., 2008; Palágyi et al., 2005) and then diluted with deionized water with ratio of 1:4 (v/v), and acidified with 2% HNO_3 (v/v). The supernatants were then analyzed for Cd using Atomic Absorption Spectroscopy (Shimadzu, AA-7000, Japan). The amount of desorbed Cd was measured by subtracting the amount of Cd

concentration in the Cd solution from the adsorption experiment from a mount of Cd concentration in the desorption solution.

RESULTS AND DISCUSSION

Physicochemical characteristics of the date seeds (DS)

The results of physicochemical parameters of DS as a raw material for biochar production showed a low moisture content (8.92%), low ash yield (1.05%), high volatile matter (78.3%), high bulk density (0.512 g/cm³), acidic with pH 4.6, and porosity (23%). The nitrogen and fixed carbon percentages were 2.13 and 21.7%, respectively (Table 1).

These results were in agreement with Mahdi et al. (2015) and El May (2012), who found that the water content of date seed were 8.95 and 5-10%, respectively. Same findings for the ash content were reported by Mahdi et al. (2015) and Bouchelta et al. (2008) who reported that the ash content of date seeds was 1.14 and 1–2%, respectively. The results of bulk density, volatile matter, and fixed carbon were proportional to the results of Mahdi et al. (2015) who found bulk density of 0.504 g/cm³, volatile matter of 65%, and fixed carbon of 24.87%.

On the basis of the above-mentioned finding from the current study, it was found that the date seeds are a good sourced raw material for biochar production.

Biochar characteristics

The results of DS biochar analysis produced under different pyrolysis temperatures (350, 450, and 550°C) showed an increase in the

pH (5.7–7.8), organic matter (75.34–98.96%), fixed carbon (43.7–57.4%), ash content (2.3–4.6%), porosity (31–69%), and the water holding capacity (WHC) (29.7–58.1%) with the increment of pyrolysis temperature from 350 to 550°C. Meanwhile, a decrease was observed in the bulk density (0.475–0.358%), biochar yield (39.7–23.6%), and nitrogen content (0.74–0.58%) with the increment of pyrolysis temperature from 350 to 550°C, respectively (Table 2) and (Figure 1A and B).

These findings were in agreement with Usman et al. (2015), who found that the yield of date seeds biochar was decreased from 49.97% at 300°C to 30.88% at 600°C with an increment in fixed carbon from 45.49 to 72.44 and ash content from 14.42 to 20.71%. Mahdi et al. (2015) find out that the pH, bulk density, and porosity of date seeds biochar were directly proportional to the pyrolysis temperature, meanwhile, the biochar yield was inversely proportional. Same trend was observed regarding the effect of pyrolysis temperature on biochar production from safflower seeds, they reported a decrease in biochar yield, increase in pH, ash, and fixed carbon with the increase of pyrolysis temperature by Angin (2013).

The SEM-EDX analyses of the DS biochar pyrolyzed at different temperatures (350, 450, and 550°C) were shown in Figure 2.

The microstructure and surface morphology structures of the DS biochar showed porous surfaces that were caused by volatilization of organic materials. The number of pores and its appearance as deep channels in biochars became clearer with increment of pyrolysis temperature. These results confirm the previous results regarding the increase in porosity proportional to the pyrolysis temperatures, which increased from 31 to 69% when the pyrolysis temperature increased from 350 to 550°C (Table 2).

The results from the current study showed that all of the elements concentrations in the DS biochar were increased with pyrolysis temperature with exception of S, as compared with the raw material (Table 3). This could mainly have related to concentrated of these elements in DS biochar samples due to temperature. Thus, these elements could not be lost by volatilization (Al-Wabel et al., 2013; Novak et al., 2009). Meanwhile, the decrease in S with increment of pyrolysis temperature could be interpreted by sulfur volatilization during pyrolysis (Al-Wabel et al., 2013).

Adsorption isotherm for Cd (Langmuir and Freundlich)

Cadmium is frequently detected in the wastewaters produced from batteries, metal, petroleum, and pesticides industries, etc. The contaminated water with cadmium could enter the environment, food chain, and thus human system. Hence, cadmium was chosen to be a model for heavy metal adsorption by DS biochar.

The Freundlich and Langmuir isotherms were applied for modeling the data of adsorbed cadmium on DS biochar. The adsorption was fitted closely to both isotherms models. The R^2 of both models were 0.9924 and 0.9628 for Langmuir and Freundlich adsorption isotherms, respectively, for the DS biochar produced at 550°C. Meanwhile, they were 0.9893 and 0.9569 for the DS biochar on 450°C and 0.9909 and 0.9535 for the DS biochar on 350°C. Therefore, the Langmuir model was considered the better apt of data, as an evidence of higher R^2 value (Figures 3, 4, and 5).

These findings were in agreement with Okeola and Odebunmi (2010) who found that Langmuir ($R^2 = 0.9999$) was more suitable than Freundlich ($R^2 =$

0.9922) to their data when studying the methylene blue adsorption by agro-waste charcoal. The adsorption of Cu on starch-based polymer was found to be more fitted with Langmuir ($R^2 = 0.9995$) than Freundlich ($R^2 = 0.8199$) (Zheng et al., 2010).

Therefore, Langmuir was employed to assess the adsorption data in the current study as reason of having higher R^2 than Freundlich.

Adsorption and desorption

The adsorption experiments for Cd by DS biochar were carried by spiking deionized water with different concentrations of cadmium. The Langmuir and Freundlich equations were applied for the data analysis. The DS biochar produced at 350, 450, and 550°C showed the capability to adsorb Cd with 667, 714, and 833 mg/kg for Langmuir and 244, 256, and 312 for Freundlich, respectively (Table 4).

The results showed that the adsorption capacity of Cd by DS biochar was increased proportionally with the biochar production temperature. These findings were in agreement with Mahdi et al. (2017), who found out that the ability of biochar to remove methylene blue from aqueous solutions

Table 4. Cadmium adsorption by DS biochar produced at different temperatures using adsorption Langmuir isotherm equations

Isotherm equations	Cadmium adsorption by DS biochar produced at different pyrolysis temperatures (mg/kg)		
	550 °C	450 °C	350 °C
Langmuir	833	714	667
Freundlich	312	256	244

correlated positively with pyrolysis temperature. The removal efficiency of Pb was the highest at the high pyrolysis temperature among the tested date seed biochars (Mahdi et al., 2018). Many works mentioned that the adsorption capability of different biochars was improved as a function of pyrolysis time and temperature.

As expected, the Langmuir equation showed higher Cd adsorption by DS biochar compared with the Freundlich equation. These findings confirm what was mentioned in the previous section regarding isotherm experiment results, where the R^2 of Langmuir was higher than in the case of Freundlich. This was in agreement with Banat et al. (2003) who found the Langmuir and Freundlich isotherm models were used successfully for the mathematical description of the sorption of cadmium ions onto carbonized date pits.

For desorption/adsorption experiment, it was carried out using the DS biochar produced at 550°C

as a reason of its higher ability to adsorb Cd more than the biochars produced at 350 and 450°C. It was found that the adsorption of Cd by DS biochar was directly proportional to the Cd concentrations. It was increased from 0.009 mmol/0.5g at 0.01 mmol Cd to 0.12 mmol/0.5g at 0.2 mmol Cd concentration (Table 5 and Figure 6). The Cd desorption from DS biochar was increased proportionally to Cd concentrations from 0.01 to 0.05 mmol. Above 0.05 mmol, the desorption was almost constant regardless to the concentration of Cd. The desorption/adsorption ratio of Cd from the DS biochar was constant also with about 16% (Table 5 and Figure 6).

These findings confirmed a high retention potential for adsorbed Cd by the DS biochar. Ahmad et al. (2012) mentioned that carbonized date seed have a high affinity to bind heavy metals, thus able to remove heavy metals from wastewater. Usman et al. (2016) found that the date palm biochar

Table 5. Cadmium adsorption, desorption, and desorption/adsorption ratio by 0.5 g biochar, the results were expressed by mean \pm SD, n = 3

Cd conc. mmol	Adsorbed Cd to biochar (mmol)	Desorbed Cd from biochar (mmol)	Cd des/ads (%)
0.01	0.01 \pm 0.0006	0.002 \pm 0.0001	15.5 \pm 0.78
0.02	0.02 \pm 0.001	0.003 \pm 0.0002	15.5 \pm 0.77

0.2	0.12 \pm 0.006	0.02 \pm 0.001	16.7 \pm 0.83

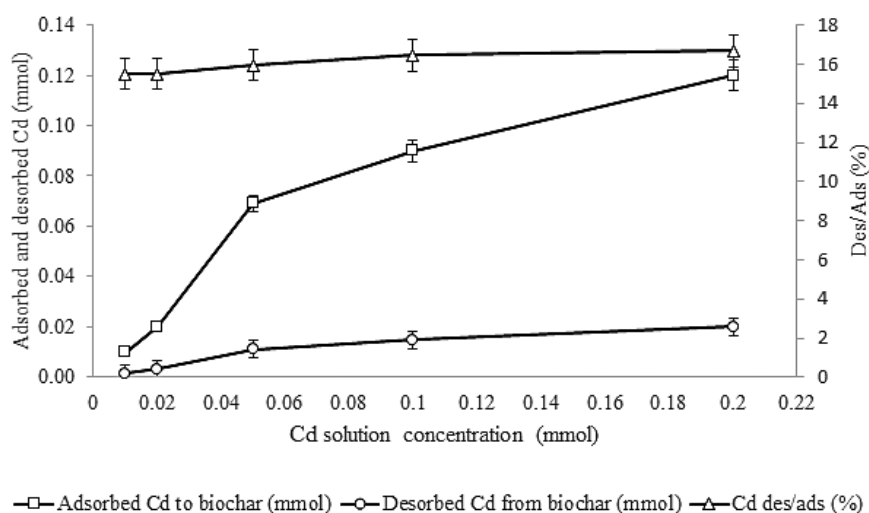

Figure 6. Cadmium adsorption, desorption, and desorption/adsorption ratio by 0.5 g DS biochar

produced at 700°C was effective in removing Cd from aqueous solution with adsorption capacity of 43.58 mg/g based on the Langmuir model. The ability of DS biochar to treat water by adsorbing Cd from the contaminated water was investigated in the current study in the adsorption experiment with artificial contaminated water, which was spiked with different Cd concentrations.

CONCLUSIONS

The current study investigated the suitability of date seeds (DS) as a raw matter for biochar production and its ability to be used in water remediation. Therefore, DS biochar was produced under different pyrolysis temperatures. DS biochar was evaluated according to its physicochemical characteristics. The biochar produced at 550°C was investigated for removing Cd from contaminated water, it was chosen according to its high porosity as well as WHC. The results found that the date seeds are a good source of raw material for biochar production. The DS biochar produced at 550°C was very active in terms of Cd removal from aqueous solutions, with low predilection toward releasing it again by desorption, which was almost 16%. Moreover, Langmuir equation showed a high capability of DS biochar to adsorb Cd with 833 mg/kg. Thus, it can be concluded that the DS biochar produced at 550°C could be considered as an active adsorbent for Cd removal from contaminated water. It is recommended to investigate and optimize the production of biochar from DS as raw matter at higher temperatures, as well as from different raw matters in any future studies. Moreover, its applications in water and soil remediation, and plant cultivation need to be in focus.
